Chapter I

Calculus on a Computer

In this first chapter we explore the basics of mathematical computing and numerical analysis. In particular we investigate the following mathematical problems which can not in general be solved exactly:

1. Integration. General integrals have no closed form expressions. Can we instead use a computer to approximate the values of definite integrals? Numerical integration underpins much of modern scientific computing and simulations of physical systems modelled by partial differential equations.

2. Differentiation. Differentiating a formula as in calculus is usually algorithmic, however, it is often needed to compute derivatives without access to an underlying formula, eg, a function defined only in code. Can we use a computer to approximate derivatives? A very important application is in Machine Learning, where there is a need to compute gradients in training neural networks.

3. Root finding. There is no general formula for finding roots (zeros) of arbitrary functions, or even polynomials that are of degree 5 (quintics) or higher. Can we compute roots of general functions using a computer?

Each chapter is divided into sections that roughly correspond to individual lectures. In this chapter we investigate solving the above computational problems:

1. I.1 Rectangular rule: we review the rectangular rule for integration and deduce the *convergence rate* of the approximation. In the lab/problem sheet we investigate its implementation as well as extensions to the Trapezium rule.

2. I.2 Divided differences: we investigate approximating derivatives by a divided difference and again deduce the convergence rates. In the lab/problem sheet we extend the approach to the central differences formula and computing second derivatives. We also observe a mystery: the approximations may have significant errors in practice, and there is a limit to the accuracy.

3. I.3 Dual numbers: we introduce the algebraic notion of a *dual number* which allows the implementation of *forward-mode automatic differentiation*, a high accuracy alternative to divided differences for computing derivatives.

4. I.4 Newton's method: Newton's method is a basic approach for computing roots/zeros of a function. We use dual numbers to implement this algorithm.

Each week there are labs and problem sheets that further explore the mathematical material introduced in each section. The labs generally explore practical implementation and the impact of implementing methods in computer arithmetic. The problem sheets dig deeper into analysis of other methods and phenomena observed in the labs. The material introduced in the labs and problem sheets is also examinable so it's important to study these as well.

I.1 Rectangular rule

One possible definition for an integral is the limit of a Riemann sum, for example:

$$\int_a^b f(x)\mathrm{d}x = \lim_{n\to\infty} h\sum_{j=1}^{n} f(x_j)$$

where $x_j = a + jh$ are evenly spaced points dividing up the interval $[a, b]$, that is with the *step size* $h = (b-a)/n$. This suggests an algorithm known as the *(right-sided) rectangular rule* for approximating an integral: choose n large so that

$$\int_a^b f(x)\mathrm{d}x \approx h\sum_{j=1}^{n} f(x_j).$$

We will show that the error in approximation is bounded by C/n for some constant C. This can be expressed using "Big-O" notation:

$$\int_a^b f(x)\mathrm{d}x = h\sum_{j=1}^{n} f(x_j) + O(1/n).$$

In these notes we consider the "Analysis" part of "Numerical Analysis": we want to *prove* the convergence rate of the approximation, including finding an explicit expression for the constant C.

To tackle this question we consider the error incurred on a single panel (x_{j-1}, x_j), then sum up the errors on rectangles.

Now for a secret. There are only so many tools available in analysis (especially at this stage of your career), and one can make a safe bet that the right tool in any analysis proof is either (1) integration-by-parts, (2) geometric series or (3) Taylor series. In this case we use (1):

Lemma 1 ((Right-sided) Rectangular Rule error on one panel)**.** *Assuming f is differentiable on $[a, b]$ and its derivative is integrable we have*

$$\int_a^b f(x)\mathrm{d}x = (b-a)f(b) + \delta$$

where $|\delta| \le M(b-a)^2$ for $M = \sup_{a\le x\le b} |f'(x)|$.

Proof We write

$$\begin{aligned}\int_a^b f(x)\mathrm{d}x &= \int_a^b (x-a)'f(x)\mathrm{d}x = [(x-a)f(x)]_a^b - \int_a^b (x-a)f'(x)\mathrm{d}x \\ &= (b-a)f(b) + \underbrace{\left(-\int_a^b (x-a)f'(x)\mathrm{d}x\right)}_{\delta}.\end{aligned}$$

Recall that we can bound the absolute value of an integral by the supremum of the integrand times the width of the integration interval:

$$\left|\int_a^b g(x)\mathrm{d}x\right| \leq (b-a)\sup_{a\leq x\leq b}|g(x)|.$$

The lemma thus follows since

$$\begin{aligned}\left|\int_a^b (x-a)f'(x)\mathrm{d}x\right| &\leq (b-a)\sup_{a\leq x\leq b}|(x-a)f'(x)| \\ &\leq (b-a)\sup_{a\leq x\leq b}|x-a|\sup_{a\leq x\leq b}|f'(x)| \\ &\leq M(b-a)^2.\end{aligned}$$

■

Now summing up the errors in each panel gives us the error of using the Rectangular rule:

Theorem 1 (Rectangular Rule error)**.** *Assuming f is differentiable on $[a,b]$ and its derivative is integrable we have*

$$\int_a^b f(x)\mathrm{d}x = h\sum_{j=1}^n f(x_j) + \delta$$

where $|\delta| \leq M(b-a)h$ for $M = \sup_{a\leq x\leq b}|f'(x)|$, $h=(b-a)/n$ and $x_j = a+jh$.

Proof We split the integral into a sum of smaller integrals:

$$\int_a^b f(x)\mathrm{d}x = \sum_{j=1}^n \int_{x_{j-1}}^{x_j} f(x)\mathrm{d}x = \sum_{j=1}^n [(x_j - x_{j-1})f(x_j) + \delta_j] = h\sum_{j=1}^n f(x_j) + \underbrace{\sum_{j=1}^n \delta_j}_{\delta}$$

where δ_j, the error on each panel as in the preceding lemma, satisfies

$$|\delta_j| \leq (x_j - x_{j-1})^2 \sup_{x_{j-1}\leq x\leq x_j}|f'(x)| \leq Mh^2.$$

Thus using the triangular inequality we have

$$|\delta| = \left|\sum_{j=1}^n \delta_j\right| \leq \sum_{j=1}^n |\delta_j| \leq Mnh^2 = M(b-a)h.$$

■

Note a consequence of this lemma is that the approximation converges as $n\to\infty$ (i.e. $h\to 0$). In the labs and problem sheets we will consider the left-sided rule:

$$\int_a^b f(x)\mathrm{d}x \approx h\sum_{j=0}^{n-1} f(x_j).$$

We also consider the *Trapezium rule*. Here we approximate an integral by an affine function:

$$\int_a^b f(x)\mathrm{d}x \approx \int_a^b \frac{(b-x)f(a)+(x-a)f(b)}{b-a}\mathrm{d}x = \frac{b-a}{2}\left[f(a)+f(b)\right].$$

Subdividing an interval $a = x_0 < x_1 < \ldots < x_n = b$ and applying this approximation separately on each subinterval $[x_{j-1}, x_j]$, where $h=(b-a)/n$ and $x_j = a+jh$, leads to the approximation

$$\int_a^b f(x)\mathrm{d}x \approx \frac{h}{2}f(a) + h\sum_{j=1}^{n-1} f(x_j) + \frac{h}{2}f(b)$$

We shall see both experimentally and provably that this approximation converges faster than the rectangular rule.

I.1.1 Lab and problem sheet

In the lab, we explore the practical implementation of the right-sided rectangular rule and extensions to other rules like the left-sided rectangular rule and trapezium rule. We also see how linear convergence ($O(h) = O(1/n)$) can be deduced *experimentally*: by comparing an implementation of the rule to specific integrals with known formulæ we can compute the error, and determine its rate of decay visually by plotting it. In particular, we deduce that the Trapezium rule converges much faster to the true value of the integral than the other rules. In the problem sheet we explore the *analysis* of these other rules, proving that the Trapezium rule converges to the true integral at a faster quadratic ($O(h^2)$) error rate. This is a guarantee that the integral can be computed much more accurately for the same amount of work by taking into account the analysis, highlighting the important contribution of analysis in the construction of algorithms.

I.2 Divided Differences

Given a function, how can we approximate its derivative at a point? We consider an intuitive approach to this problem using *(Right-sided) Divided Differences*:

$$f'(x) \approx \frac{f(x+h) - f(x)}{h}$$

Note by the definition of the derivative we know that this approximation will converge to the true derivative as $h \to 0$. But in numerical approximations we also need to consider the rate of convergence.

Now in the previous section I mentioned there are three basic tools in analysis: (1) integration-by-parts, (2) geometric series or (3) Taylor series. In this case we use (3):

Proposition 1 (divided differences error)**.** *Suppose that f is twice-differentiable on the interval $[x, x+h]$. The error in approximating the derivative using divided differences is*

$$f'(x) = \frac{f(x+h) - f(x)}{h} + \delta$$

where $|\delta| \leq Mh/2$ for $M = \sup_{x \leq t \leq x+h} |f''(t)|$.

Proof Follows immediately from Taylor's theorem: recall that

$$f(x+h) = f(x) + f'(x)h + \frac{f''(t)}{2}h^2$$

for some $t \in [x, x+h]$. Rearranging we get

$$f'(x) = \frac{f(x+h) - f(x)}{2} + \underbrace{\left(-\frac{f''(t)}{2h^2}\right)}_{\delta}.$$

We then bound:

$$|\delta| \leq \left|\frac{f''(t)}{2}h\right| \leq \frac{Mh}{2}.$$

■

Unlike the rectangular rule, the computational cost of computing the divided difference is independent of h! We only need to evaluate a function f twice and do a single division. Here we are assuming that the computational cost of evaluating f is independent of the point of evaluation. Later we will investigate the details of how computers work with numbers via floating point, and confirm that this is a sensible assumption.

In the lab we investigate the convergence rate of these approximations (in particular, that central differences is more accurate than standard divided differences) and observe that they too suffer from unexplained (for now) loss of accuracy as $h \to 0$. In the problem sheet we prove the theoretical convergence rate, which is never realised because of these errors.

I.2.1 Lab and problem sheet

In the labs and problem sheets we explore alternative versions of divided differences. Left-side divided differences evaluates to the left of the point where we wish to know the derivative:

$$f'(x) \approx \frac{f(x) - f(x-h)}{h}$$

and central differences evaluates both left and right:

$$f'(x) \approx \frac{f(x+h) - f(x-h)}{2h}.$$

We can further arrive at an approximation to the second derivative by composing a left- and right-sided finite difference:

$$f''(x) \approx \frac{f'(x+h) - f'(x)}{h} \approx \frac{\frac{f(x+h)-f(x)}{h} - \frac{f(x)-f(x-h)}{h}}{h} = \frac{f(x+h) - 2f(x) + f(x-h)}{h^2}.$$

The lab explores these approximations *experimentally*, and we will observe that central differences converges much faster to the true value of the derivative as h becomes moderately small.

An important distinction between rectangular rules and divided difference is that the computational cost of divided differences is independent of h: we can choose h arbitrarily and the approximation will take the same amount of time. This raises a question: why not just set h ridiculously small so that the approximation is extremely accurate? Unfortunately, we will observe in the lab a serious issue: if h becomes too small, the error mysteriously starts to grow, and hence these rules do not actually converge to the true value of the derivatives! Thus there is a limitation to how accurate one can approximate a derivative using divided differences, an issue we will overcome in the next section by re-thinking derivatives in an algebraic way.

The problem sheet explores the *analysis* of divided difference rules, proving the precise theoretical convergence rates observed for moderately small h. This presents a bit of a conundrum: why does the theory say the method converges but in practice it diverges, and spectacularly so! This is a mystery that we will return to later, by understanding how computer arithmetic with real numbers works.

I.3 Dual Numbers

In this section we introduce a mathematically beautiful alternative to divided differences for computing derivatives: *dual numbers*. These are a commutative ring that *exactly* compute

derivatives, which when implemented on a computer gives very high-accuracy approximations to derivatives. They underpin forward-mode automatic differentation. Automatic differentiation is a basic tool in Machine Learning for computing gradients necessary for training neural networks.

Definition 1 (Dual numbers)**.** Dual numbers $\mathbb{D}$ are a commutative ring (over $\mathbb{R}$) generated by 1 and ϵ such that $\epsilon^2 = 0$, that is,

$$\mathbb{D} := \{a + b\epsilon \quad : \quad a, b \in \mathbb{R}, \quad \epsilon^2 = 0\}.$$

This is very much analoguous to complex numbers, which are a field generated by 1 and i such that $\mathrm{i}^2 = -1$, that is,

$$\mathbb{C} := \{a + b\mathrm{i} \quad : \quad a, b \in \mathbb{R}, \quad \mathrm{i}^2 = -1\}.$$

Compare multiplication of each number type which falls out of the rules of the generators:

$$\begin{aligned}(a + b\mathrm{i})(c + d\mathrm{i}) &= ac + (bc + ad)\mathrm{i} + bd\mathrm{i}^2 = ac - bd + (bc + ad)\mathrm{i},\\ (a + b\epsilon)(c + d\epsilon) &= ac + (bc + ad)\epsilon + bd\epsilon^2 = ac + (bc + ad)\epsilon.\end{aligned}$$

And just as we view $\mathbb{R} \subset \mathbb{C}$ by equating $a \in \mathbb{R}$ with $a + 0\mathrm{i} \in \mathbb{C}$, we can view $\mathbb{R} \subset \mathbb{D}$ by equating $a \in \mathbb{R}$ with $a + 0\epsilon \in \mathbb{D}$.

Conceptually, dual numbers can be thought of as introducing an infinitesimally small ϵ, where ϵ^2 is so small it is treated as zero. This is the intuitive reason they allow for differentiation of functions. But we do not need to appeal to this calculus-like interpretation, instead, their construction and relationship to differentiation can be accomplished using purely algebraic reasoning.

I.3.1 Differentiating polynomials

Polynomials evaluated on dual numbers are well-defined as they depend only on the operations $+$ and $*$. From the formula for multiplication of dual numbers we deduce that evaluating a polynomial at a dual number $a + b\epsilon$ tells us the derivative of the polynomial at a:

Theorem 2 (polynomials on dual numbers)**.** *Suppose p is a polynomial. Then*

$$p(a + b\epsilon) = p(a) + bp'(a)\epsilon$$

Proof

First consider $p(x) = x^n$ for $n \geq 0$. The cases $n = 0$ and $n = 1$ are immediate. For $n > 1$ we have by induction:

$$(a + b\epsilon)^n = (a + b\epsilon)(a + b\epsilon)^{n-1} = (a + b\epsilon)(a^{n-1} + (n - 1)ba^{n-2}\epsilon) = a^n + bna^{n-1}\epsilon.$$

For a more general polynomial

$$p(x) = \sum_{k=0}^{n} c_k x^k$$

the result follows from linearity:

$$p(a+b\varepsilon) = \sum_{k=0}^{n} c_k(a+b\epsilon)^k = c_0+\sum_{k=1}^{n} c_k(a^k+kba^{k-1}\epsilon) = \sum_{k=0}^{n} c_k a^k+b\sum_{k=1}^{n} c_k k a^{k-1}\epsilon = p(a)+bp'(a)\epsilon.$$

■

Example 1 (differentiating polynomial)**.** Consider computing $p'(2)$ where

$$p(x) = (x-1)(x-2) + x^2.$$

We can use dual numbers to differentiate, avoiding expanding in monomials or applying rules of differentiating:

$$p(2+\epsilon) = (1+\epsilon)\epsilon + (2+\epsilon)^2 = \epsilon + 4 + 4\epsilon = 4 + \underbrace{5}_{p'(2)}\epsilon.$$

I.3.2 Differentiating other functions

We can extend real-valued differentiable functions to dual numbers in a similar manner. First, consider a standard function with a Taylor series (e.g. cos, sin, exp, etc.)

$$f(x) = \sum_{k=0}^{\infty} f_k x^k$$

so that a is inside the radius of convergence. This leads naturally to a definition on dual numbers:

$$\begin{aligned} f(a+b\epsilon) &= \sum_{k=0}^{\infty} f_k (a+b\epsilon)^k = f_0 + \sum_{k=1}^{\infty} f_k (a^k + k a^{k-1} b\epsilon) = \sum_{k=0}^{\infty} f_k a^k + \sum_{k=1}^{\infty} f_k k a^{k-1} b\epsilon \\ &= f(a) + bf'(a)\epsilon. \end{aligned}$$

More generally, given a differentiable function (which may not have a Taylor series) we can extend it to dual numbers:

Definition 2 (dual extension)**.** Suppose a real-valued function $f : \Omega \to \mathbb{R}$ is differentiable in $\Omega \subset \mathbb{R}$. We can construct the *dual extension* $\underline{f} : \Omega + \epsilon\mathbb{R} \to \mathbb{D}$ by defining

$$\underline{f}(a+b\epsilon) := f(a) + bf'(a)\epsilon.$$

By viewing $\mathbb{R} \subset \mathbb{D}$, it is natural to reuse the notation f for the dual extension, hence when there's no chance of confusion we will identify $f(a+b\epsilon) \equiv \underline{f}(a+b\epsilon)$.

Thus, for basic functions we have natural extensions:

$$\begin{aligned} \exp(a+b\epsilon) &:= \exp(a) + b\exp(a)\epsilon && (a,b \in \mathbb{R}) \\ \sin(a+b\epsilon) &:= \sin(a) + b\cos(a)\epsilon && (a,b \in \mathbb{R}) \\ \cos(a+b\epsilon) &:= \cos(a) - b\sin(a)\epsilon && (a,b \in \mathbb{R}) \\ \log(a+b\epsilon) &:= \log(a) + \frac{b}{a}\epsilon && (a \in (0,\infty), b \in \mathbb{R}) \\ \sqrt{a+b\epsilon} &:= \sqrt{a} + \frac{b}{2\sqrt{a}}\epsilon && (a \in (0,\infty), b \in \mathbb{R}) \\ |a+b\epsilon| &:= |a| + b\,\mathrm{sign}a\,\epsilon && (a \in \mathbb{R}\backslash\{0\}, b \in \mathbb{R}) \end{aligned}$$

provided the function is differentiable at a. Note the last example does not have a convergent Taylor series (at 0) but we can still extend it where it is differentiable.

Going further, we can add, multiply, and compose such dual-extensions. And the beauty is these automatically satisfy the right properties to be dual-extensions themselves, thus

allowing for differentiation of complicated functions built from basic differentiable building blocks.

The following lemma shows that addition and multiplication in some sense "commute" with the dual-extension, hence we can recover the product rule from dual number multiplication:

Lemma 2 (addition/multiplication)**.** *Suppose $f, g : \Omega \to \mathbb{R}$ are differentiable for $\Omega \subset \mathbb{R}$ and $c \in \mathbb{R}$. Then for $a \in \Omega$ and $b \in \mathbb{R}$ we have*

$$\begin{aligned} \underline{f+g}(a+b\epsilon) &= \underline{f}(a+b\epsilon) + \underline{g}(a+b\epsilon) \\ \underline{cf}(a+b\epsilon) &= c\underline{f}(a+b\epsilon) \\ \underline{fg}(a+b\epsilon) &= \underline{f}(a+b\epsilon)\underline{g}(a+b\epsilon) \end{aligned}$$

Proof The first two are immediate due to linearity:

$$\begin{aligned} \underline{(f+g)}(a+b\epsilon) &= (f+g)(a) + b(f+g)'(a)\epsilon \\ &= (f(a) + bf'(a)\epsilon) + (g(a) + bg'(a)\epsilon) = \underline{f}(a+b\epsilon) + \underline{g}(a+b\epsilon), \\ \underline{cf}(a+b\epsilon) &= (cf)(a) + b(cf)'(a)\epsilon = c(f(a) + bf'(a)\epsilon) = c\underline{f}(a+b\epsilon). \end{aligned}$$

The last property essentially captures the product rule of differentiation:

$$\begin{aligned} \underline{fg}(a+b\epsilon) &= f(a)g(a) + b(f(a)g'(a) + f'(a)g'(a))\epsilon \\ &= (f(a) + bf'(a)\epsilon)(g(a) + bg'(a)\epsilon) = \underline{f}(a+b\epsilon)\underline{g}(a+b\epsilon). \end{aligned}$$

■

Furthermore composition recovers the chain rule:

Lemma 3 (composition)**.** *Suppose $f : \Gamma \to \mathbb{R}$ and $g : \Omega \to \Gamma$ are differentiable in $\Omega, \Gamma \subset \mathbb{R}$. Then*

$$\underline{(f \circ g)}(a+b\epsilon) = \underline{f}(\underline{g}(a+b\epsilon))$$

Proof Again it falls out of the properties of dual numbers:

$$\underline{(f \circ g)}(a+b\epsilon) = f(g(a)) + bg'(a)f'(g(a))\epsilon = \underline{f}(g(a) + bg'(a)\epsilon) = \underline{f}(\underline{g}(a+b\epsilon))$$

■

A simple corollary is that any function defined in terms of addition, multiplication, composition, etc. of basic functions with dual-extensions will be differentiable via dual numbers. In this following example we see a practical realisation of this, where we differentiate a function by just evaluating it on dual numbers, implicitly, using the dual-extension for the basic build blocks:

Example 2 (differentiating non-polynomial)**.** Consider differentiating $f(x) = \exp(x^2 + \cos x)$ at the point $a = 1$, where we automatically use the dual-extension of exp and cos. We can differentiate f by simply evaluating on the duals:

$$f(1+\epsilon) = \exp(1 + 2\epsilon + \cos 1 - \sin 1\epsilon) = \exp(1 + \cos 1) + \exp(1 + \cos 1)(2 - \sin 1)\epsilon.$$

Therefore we deduce that

$$f'(1) = \exp(1 + \cos 1)(2 - \sin 1).$$

I.3.3 Lab and problem sheet

In the lab we explore how one can turn this mathematical idea into a practical implementation on a computer, giving a basic version of *forward-mode automatic differentiation*. This is a concept that underpins machine learning, which uses *reverse-mode automatic differentiation* to compute gradients when performing stochastic gradient descent. In order to implement dual numbers, we will introduce the concept of a *type*: a data structure with fields. For example, we will implement a type `Rat` for representing rationals p/q, where the type has two fields (`p` and `q`). Basic arithmetic operations like `+` and `*` can be implemented to correctly do rational arithmetic. We will then create a new type that can represent a dual number $a + b\epsilon$, where the the type has two fields (`a` and `b`). By implementing basic arithmetic operations as well as more complicated functions like `exp` we can efficiently, and extremely accurately, compute derivatives of quite general functions.

In the problem sheet, we explore how dual numbers can also be used for pen-and-paper calculations of derivatives. This gives an alternative to traditional differentiation rules like chain and product rule, that while it is mathematically equivalent feels very different in practice. (I prefer it because it is much more algorithmic!) Make sure when doing the problem sheet to only use dual numbers and not fall back to the more traditional rules. We also see that one can extend the concept to a 2D-analogue of dual numbers, which allows for computation of gradients.

I.4 Newton's method

In school you may recall learning Newton's method: a way of approximating zeros/roots to a function by using a local approximation by an affine function. That is, approximate a function $f(x)$ locally around an initial guess x_0 by its first order Taylor series:

$$f(x) \approx f(x_0) + f'(x_0)(x - x_0)$$

and then find the root of the right-hand side which is

$$f(x_0) + f'(x_0)(x - x_0) = 0 \Leftrightarrow x = x_0 - \frac{f(x_0)}{f'(x_0)}.$$

We can then repeat using this root as the new initial guess. In other words we have a sequence of *hopefully* more accurate approximations:

$$x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)}.$$

Thus *if* we can compute derivatives, we can (sometimes) compute roots.

In terms of analysis, we can guarantee convergence provided our initial guess is accurate enough. The first step is the bound the error of an iteration in terms of the previous error:

Theorem 3 (Newton error)**.** *Suppose f is twice-differentiable in a neighbourhood B of r such that $f(r) = 0$, and f' does not vanish in B. Denote the error of the k-th Newton iteration as $\varepsilon_k := r - x_k$. If $x_k \in B$ then*

$$|\varepsilon_{k+1}| \leq M|\varepsilon_k|^2$$

where

$$M := \frac{1}{2} \sup_{x \in B} |f''(x)| \sup_{x \in B} \left| \frac{1}{f'(x)} \right|.$$

Proof Using Taylor's theorem we find that

$$0 = f(r) = f(x_k + \varepsilon_k) = f(x_k) + f'(x_k)\varepsilon_k + \frac{f''(t)}{2}\varepsilon_k^2.$$

for some $t \in B$ between r and x_k. Rearranging this we get an expression for $f(x_k)$ that tells us that

$$\varepsilon_{k+1} = r - \underbrace{x_{k+1}}_{x_k - f(x_k)/f'(x_k)} = \varepsilon_k + \frac{f(x_k)}{f'(x_k)} = -\frac{f''(t)}{2f'(x_k)}\varepsilon_k^2.$$

Taking absolute values of each side gives the result.

■

This result says that the error decays *quadratically*, which in this case means that the number of digits roughly doubles each iteration. That is, if the error and one step is about 10^{-3} then the error at the next step is about 10^{-6} and the step after about 10^{-12}: this is a drastic improvement! Hidden in this result is a guarantee of convergence provided x_0 is sufficiently close to r.

Corollary 1 (Newton convergence)**.** *If $x_0 \in B$ is sufficiently close to r then $x_k \to r$.*

Proof

Suppose $x_k \in B$ satisfies $|\varepsilon_k| = |r - x_k| \leq M^{-1}$. Then

$$|\varepsilon_{k+1}| \leq M|\varepsilon_k|^2 \leq |\varepsilon_k|,$$

hence $x_{k+1} \in B$. Thus from induction if x_0 satisfies the condition $|\varepsilon_0| < M^{-1}$ condition then $x_k \in B$ for all k and satisfies $|\varepsilon_k| \leq M^{-1}$. Thus we find (for large enough k)

$$|\varepsilon_k| \leq M|\varepsilon_{k-1}|^2 \leq M^3|\varepsilon_{k-2}|^4 \leq M^7|\varepsilon_{k-3}|^8 \leq \ldots \leq M^{2^k-1}|\varepsilon_0|^{2^k} = \frac{1}{M}(M|\varepsilon_0|)^{2^k}.$$

Provided x_0 satisfies the strict inequality $|\varepsilon_0| < M^{-1}$ this will go to zero as $k \to \infty$.

■

I.4.1 Lab and problem sheet

In the lab we explore using Newton's method for some simple root finding problems. We also see that automatic differentiation via dual numbers can be used effectively to compute the derivatives. This is in some sense a baby version of how Machine Learning algorithms train neural networks; but whilst Newton uses derivatives (or in higher-dimensions, gradients) to find roots of functions Machine Learning uses gradients to (very roughly) minimise functions that represent the error between a neural network and training data. Minimisation problems are very closely related to root finding problems (essentially the minima are associated with roots of the gradient) and there are specialised training algorithms in ML built on a randomised version of Newton's method.

In the problem sheet we see how the error bound for Newton iteration can be extended to the degenerate case where the second derivative also vanishes, but now we no longer achieve quadratic convergence, but it still decays exponentially with the number of iterations (which is called *linear convergence*).

Chapter II

Representing Numbers

In this chapter we aim to answer the question: when can we rely on computations done on a computer? Why are some computations (differentiation via divided differences), extremely inaccurate whilst others (integration via rectangular rule) accurate up to about 16 digits? In order to address these questions we need to dig deeper and understand at a basic level what a computer is actually doing when manipulating numbers.

Before we begin it is important to have a basic model of how a computer works. Our simplified model of a computer will consist of a Central Processing Unit (CPU)—the brains of the computer—and Memory—where data is stored. Inside the CPU there are registers, where data is temporarily stored after being loaded from memory, manipulated by the CPU, then stored back to memory. Memory is a sequence of bits: `1`s and `0`s, essentially "on/off" switches, and memory is *finite*. Finally, if one has a p-bit CPU (eg a 32-bit or 64-bit CPU), each register consists of exactly p-bits. Most likely $p = 64$ on your machine.

Thus representing numbers on a computer must overcome three fundamental limitations:

1. CPUs can only manipulate data p-bits at a time.
2. Memory is finite (in particular at most 2^p bytes).
3. There is no such thing as an "error": if anything goes wrong in the computation we must use some of the p-bits to indicate this.

This is clearly problematic: there are an infinite number of integers and an uncountable number of reals! Each of which we need to store in precisely p-bits. Moreover, some operations are simply undefined, like division by 0. This chapter discusses the solution used to this problem, alongside the mathematical analysis that is needed to understand the implications, in particular, that computations have *error*.

In particular we discuss:

1. II.1 Reals: real numbers are approximated by floating point numbers, which are a computers version of scientific notation.
2. II.2 Floating Point Arithmetic: arithmetic with floating point numbers is exact up-to-rounding, which introduces small-but-understandable errors in the computations. We explain how these errors can be analysed mathematically to get rigorous bounds.

3. II.3 Interval Arithmetic: rounding can be controlled in order to implement *interval arithmetic*, a way to compute rigorous bounds for computations. In the lab, we use this to compute up to 15 digits of $\mathrm{e} \equiv \exp 1$ rigorously with precise bounds on the error.

II.1 Reals

In this chapter, we introduce the IEEE Standard for Floating-Point Arithmetic. There are multiplies ways of representing real numbers on a computer, as well as the precise behaviour of operations such as addition, multiplication, etc. One can use

1. Fixed-point arithmetic: essentially representing a real number as an integer where a decimal point is inserted at a fixed position. This turns out to be impractical in most applications, e.g., due to loss of relative accuracy for small numbers.
2. Floating-point arithmetic: essentially scientific notation where an exponent is stored alongside a fixed number of digits. This is what is used in practice.
3. Level-index arithmetic: stores numbers as iterated exponents. This is the most beautiful mathematically but unfortunately is not as useful for most applications and is not implemented in hardware.

Before the 1980s each processor had potentially a different representation for floating-point numbers, as well as different behaviour for operations. IEEE introduced in 1985 standardised this across processors so that algorithms would produce consistent and reliable results.

This chapter may seem very low level for a mathematics course but there are two important reasons to understand the behaviour of floating-point numbers in details:

1. Floating-point arithmetic is precisely defined, and can even be used in rigorous computations as we shall see in the labs. But it is not exact and its important to understand how errors in computations can accumulate.
2. Failure to understand floating-point arithmetic can cause catastrophic issues in practice, with the extreme example being the explosion of the Ariane 5 rocket.

II.1.1 Real numbers in binary

We begin by describing how both integers and real numbers can be written in binary, that is, base-2. In this case the digits are either 0 or 1, which matches how a computer stores data.

Integers can be written in binary as follows:

Definition 3 (binary format)**.** For $B_0, \ldots, B_p \in \{0, 1\}$ denote an integer in *binary format* by:

$$\pm(B_p \ldots B_1 B_0)_2 := \pm \sum_{k=0}^{p} B_k 2^k$$

Reals can also be presented in binary format, that is, a sequence of `0`s and `1`s alongside a decimal point:

Definition 4 (real binary format)**.** For $b_1, b_2, \ldots \in \{0, 1\}$, Denote a non-negative real number in *binary format* by:

$$(B_p \ldots B_0.b_1b_2b_3\ldots)_2 := (B_p \ldots B_0)_2 + \sum_{k=1}^{\infty} \frac{b_k}{2^k}.$$

Example 3 (rational in binary)**.** Consider the number `1/3`. In decimal recall that:

$$1/3 = 0.3333\ldots = \sum_{k=1}^{\infty} \frac{3}{10^k}$$

We will see that in binary

$$1/3 = (0.010101\ldots)_2 = \sum_{k=1}^{\infty} \frac{1}{2^{2k}}$$

Both results can be proven using the geometric series:

$$\sum_{k=0}^{\infty} z^k = \frac{1}{1-z}$$

provided $|z| < 1$. That is, with $z = \frac{1}{4}$ we verify the binary expansion:

$$\sum_{k=1}^{\infty} \frac{1}{4^k} = \frac{1}{1-1/4} - 1 = \frac{1}{3}$$

A similar argument with $z = 1/10$ shows the decimal case.

II.1.2 Floating-point numbers

Floating-point numbers are a subset of real numbers that are representable using a fixed number of bits.

Definition 5 (floating-point numbers)**.** Given integers σ (the *exponent shift*), Q (the number of *exponent bits*) and S (the *precision*), define the set of *Floating-point numbers* by as the union of *normal*, *sub-normal*, and *special* floating point numbers:

$$F_{\sigma,Q,S} := F^{\text{normal}}_{\sigma,Q,S} \cup F^{\text{sub}}_{\sigma,Q,S} \cup F^{\text{special}}.$$

The *normal numbers* $F^{\text{normal}}_{\sigma,Q,S} \subset \mathbb{R}$ are

$$F^{\text{normal}}_{\sigma,Q,S} := \{\pm 2^{q-\sigma} \times (1.b_1b_2b_3\ldots b_S)_2 : 1 \le q < 2^Q - 1\}.$$

The *sub-normal numbers* $F^{\text{sub}}_{\sigma,Q,S} \subset \mathbb{R}$ are

$$F^{\text{sub}}_{\sigma,Q,S} := \{\pm 2^{1-\sigma} \times (0.b_1b_2b_3\ldots b_S)_2\}.$$

The *special numbers* $F^{\text{special}} \not\subset \mathbb{R}$ are

$$F^{\text{special}} := \{\infty, -\infty, \text{NaN}\}$$

where NaN is a special symbol representing "not a number", essentially an error flag.

Note this set of real numbers has no nice *algebraic structure*: it is not closed under addition, subtraction, etc. On the other hand, we can control errors effectively hence it is extremely useful for analysis.

Floating-point numbers are stored in $1 + Q + S$ total number of bits, in the format

$$s \; q_{Q-1} \dots q_0 \; b_1 \dots b_S$$

The first bit (s) is the *sign bit*: 0 means positive and 1 means negative. The bits $q_{Q-1} \dots q_0$ are the *exponent bits*: they are the binary digits of the unsigned integer q:

$$q = (q_{Q-1} \dots q_0)_2.$$

Finally, the bits $b_1 \dots b_S$ are the *significand bits*. If $1 \leq q < 2^Q - 1$ then the bits represent the normal number

$$x = \pm 2^{q-\sigma} \times (1.b_1 b_2 b_3 \dots b_S)_2.$$

If $q = 0$ (i.e. all bits are 0) then the bits represent the sub-normal number

$$x = \pm 2^{1-\sigma} \times (0.b_1 b_2 b_3 \dots b_S)_2.$$

If $q = 2^Q - 1$ (i.e. all bits are 1) then the bits represent a special number. If all sigificand bits are 0 then it represents $\pm\infty$. Otherwise if any significand bit is 1 then it represents `NaN`.

Remark A common point of confusion is the difference between a *number* whose digits are 0 and 1 but may have a sign ($\pm$) and a decimal point and a *sequence of bits*, which is how a number is stored in memory in a computer.

II.1.3 IEEE floating-point numbers

Definition 6 (IEEE floating-point numbers)**.** IEEE has 3 standard floating-point formats: 16-bit (half precision), 32-bit (single precision) and 64-bit (double precision) defined by (you *do not* need to memorise these):

$$F_{16} := F_{15,5,10}$$
$$F_{32} := F_{127,8,23}$$
$$F_{64} := F_{1023,11,52}$$

We now see a simple example of relating the bits of a floating point number with the number it represents:

Example 4 (interpreting 16-bits as a float)**.** Consider the number with bits

$$0 \; 10000 \; 1010000000$$

assuming it is a half-precision float (F_{16}). Since the sign bit is `0` it is positive. The exponent bits encode

$$q = (10000)_2 = 2^4$$

hence the exponent is

$$q - \sigma = 2^4 - 15 = 1$$

and the number is:

$$2^1 (1.1010000000)_2 = 2(1 + 1/2 + 1/8) = 3 + 1/4 = 3.25.$$

Example 5 (rational to 16-bits)**.** How is the number 1/3 stored in F_{16}? Recall that

$$1/3 = (0.010101\ldots)_2 = 2^{-2}(1.0101\ldots)_2 = 2^{13-15}(1.0101\ldots)_2$$

and since $13 = (1101)_2$ the exponent bits are `01101`. For the significand we round the last bit to the nearest element of F_{16}, (the exact rule for rounding is explained in detail later), so we have

$$1.01010101010101010101010101\ldots \approx 1.0101010101 \in F_{16}$$

and the significand bits are `0101010101`. Thus the stored bits for 1/3 are:

0 01101 0101010101

II.1.4 Sub-normal and special numbers

For sub-normal numbers, the simplest example is zero, which has $q = 0$ and all significand bits zero: `0 00000 0000000000`. Unlike integers, we also have a negative zero, which has bits: `1 00000 0000000000`. This is treated as identical to positive `0` (except for degenerate operations as explained in the lab).

Example 6 (subnormal in 16-bits)**.** Consider the number with bits

1 00000 1100000000

assuming it is a half-precision float (F_{16}). Since all exponent bits are zero it is sub-normal. Since the sign bit is `1` it is negative. Hence this number is:

$$-2^{1-\sigma}(0.1100000000)_2 = -2^{-14}(2^{-1} + 2^{-2}) = -3 \times 2^{-16}$$

The special numbers extend the real line by adding $\pm\infty$ but also a notion of "not-a-number" NaN. Whenever the bits of q of a floating-point number are all 1 then they represent an element of F^{special}. If all $b_k = 0$, then the number represents either $\pm\infty$. All other special floating-point numbers represent NaN.

Example 7 (special in 16-bits)**.** The number with bits

1 11111 0000000000

has all exponent bits equal to 1, and significand bits 0 and sign bit 1, hence represents $-\infty$. On the other hand, the number with bits

1 11111 0000000001

has all exponent bits equal to 1 but does not have all significand bits equal to 0, hence is one of many representations for NaN.

II.1.5 Lab and problem sheet

In the lab we explore how integers and floating point numbers are stored in a computer via different *type*s. We begin with a description both signed and unsigned integers, whose mathematical behaviour are detailed in the (non-examinable) appendix. We see how different

sequences of bits can be reinterpreted as different numbers, and explore using string manipulation to construct different types of numbers. We also see how integers can sometimes be output in hexadecimal (base-16) format, which aligns better with the underlying binary storage. We then explore floating point numbers including construction by specifying the bits directly. We finally investigate some of the degenerate behaviour such as arithmetic with special numbers. In the problem sheet we investigate some simple examples of representing numbers in floating point format.

II.2 Floating Point Arithmetic

We now turn our attention to how arithmetic operations (`+`, `*`, `-`, `/`, etc.) work with floating point arithmetic, in particular, how they cope with the fact that some calculations involving floating point numbers result in numbers that are not floating point (like `1/3`). The answer is that arithmetic operations on floating-point numbers are rounded, and are guaranteed to be *exact up to rounding*. There are three basic rounding strategies: round up/down/nearest. Mathematically we introduce a function to capture the notion of rounding:

Definition 7 (rounding)**.** The function $\mathrm{fl}^{\mathrm{up}}_{\sigma,Q,S} : \mathbb{R} \to F_{\sigma,Q,S}$ rounds a real number up to the nearest floating-point number that is greater than or equal:

$$\mathrm{fl}^{\mathrm{up}}_{\sigma,Q,S}(x) := \min\{y \in F_{\sigma,Q,S} : y \geq x\}.$$

The function $\mathrm{fl}^{\mathrm{down}}_{\sigma,Q,S} : \mathbb{R} \to F_{\sigma,Q,S}$ rounds a real number down to the nearest floating-point number that is less than or equal:

$$\mathrm{fl}^{\mathrm{down}}_{\sigma,Q,S}(x) := \max\{y \in F_{\sigma,Q,S} : y \leq x\}.$$

The function $\mathrm{fl}^{\mathrm{nearest}}_{\sigma,Q,S} : \mathbb{R} \to F_{\sigma,Q,S}$ denotes the function that rounds a real number to the nearest floating-point number. In case of a tie, it returns the floating-point number whose least significant bit is equal to zero. We use the notation fl when σ, Q, S and the rounding mode are implied by context, with $\mathrm{fl}^{\mathrm{nearest}}$ being the default rounding mode.

In more detail on the behaviour of nearest mode, if a positive number x is between two normal floats $x_- \leq x \leq x_+$ we can write its expansion as

$$x = 2^{q-\sigma}(1.b_1b_2\ldots b_S b_{S+1}\ldots)_2$$

where

$$\begin{aligned} x_- &:= \mathrm{fl}^{\mathrm{down}}(x) = 2^{q-\sigma}(1.b_1b_2\ldots b_S)_2 \\ x_+ &:= \mathrm{fl}^{\mathrm{up}}(x) = x_- + 2^{q-\sigma-S} \end{aligned}$$

Write the half-way point as:

$$x_{\mathrm{h}} := \frac{x_+ + x_-}{2} = x_- + 2^{q-\sigma-S-1} = 2^{q-\sigma}(1.b_1b_2\ldots b_S 1)_2$$

If $x_- \leq x < x_{\mathrm{h}}$ then $\mathrm{fl}(x) = x_-$ and if $x_{\mathrm{h}} < x \leq x_+$ then $\mathrm{fl}(x) = x_+$. If $x = x_{\mathrm{h}}$ then it is exactly half-way between x_- and x_+. The rule is if $b_S = 0$ then $\mathrm{fl}(x) = x_-$ and otherwise $\mathrm{fl}(x) = x_+$.

In IEEE arithmetic, the arithmetic operations `+`, `-`, `*`, `/` are defined by the property that they are exact up to rounding. Mathematically we denote these operations as $\oplus, \ominus, \otimes, \oslash : F_{\sigma,Q,S} \times F_{\sigma,Q,S} \to F_{\sigma,Q,S}$ as follows:

$$\begin{aligned} x \oplus y &:= \text{fl}(x + y) \\ x \ominus y &:= \text{fl}(x - y) \\ x \otimes y &:= \text{fl}(x * y) \\ x \oslash y &:= \text{fl}(x/y) \end{aligned}$$

Note also that `^` and `sqrt` are similarly exact up to rounding. Also, note that when we convert a Julia command with constants specified by decimal expansions we first round the constants to floats, e.g., `1.1 + 0.1` is actually reduced to

$$\text{fl}(1.1) \oplus \text{fl}(0.1)$$

This includes the case where the constants are integers (which are normally exactly floats but may be rounded if extremely large).

Example 8 (decimal is not exact)**.** On a computer `1.1+0.1` is close to but not exactly the same thing as `1.2`. This is because $\text{fl}(1.1) \neq 1 + 1/10$ and $\text{fl}(0.1) \neq 1/10$ since their expansion in *binary* is not finite. For F_{16} we have:

$$\begin{aligned} &\text{fl}(1.1) = \text{fl}((1.0001100110011\ldots)_2) = (1.0001100110)_2 \\ &\text{fl}(0.1) = \text{fl}(2^{-4}(1.1001100110011\ldots)_2) = 2^{-4} * (1.1001100110)_2 = (0.00011001100110)_2 \end{aligned}$$

Thus when we add them we get

$$\text{fl}(1.1) + \text{fl}(0.1) = (1.0011001100011)_2$$

where the red digits indicate those beyond the 10 significant digits representable in F_{16}. In this case we round down and get

$$\text{fl}(1.1) \oplus \text{fl}(0.1) = (1.0011001100)_2$$

On the other hand,

$$\text{fl}(1.2) = \text{fl}((1.0011001100110011100\ldots)_2) = (1.0011001101)_2$$

which differs by 1 bit.

WARNING (non-associative) These operations are not associative! E.g. $(x \oplus y) \oplus z$ is not necessarily equal to $x \oplus (y \oplus z)$. Commutativity is preserved, at least.

II.2.1 Bounding errors in floating point arithmetic

We will now see that the error introduced by rounding can be bounded, giving a means to guarantee that some algorithms yield accurate results despite the errors introduced. When dealing with normal numbers there are some important constants that we will use to bound errors.

Definition 8 (machine epsilon/smallest positive normal number/largest normal number)**.** *Machine epsilon* is denoted

$$\epsilon_{\mathrm{m},S} := 2^{-S}.$$

When S is implied by context we use the notation ϵ_{m}. The *smallest positive normal number* is $q = 1$ and b_k all zero:

$$\min |F^{\mathrm{normal}}_{\sigma,Q,S}| = 2^{1-\sigma}$$

where $|A| := \{|x| : x \in A\}$. The *largest (positive) normal number* is

$$\max F^{\mathrm{normal}}_{\sigma,Q,S} = 2^{2^Q-2-\sigma}(1.11\ldots)_2 = 2^{2^Q-2-\sigma}(2-\epsilon_{\mathrm{m}})$$

We can bound the error of basic arithmetic operations in terms of machine epsilon, provided a real number is close to a normal number:

Definition 9 (normalised range)**.** The *normalised range* $\mathcal{N}_{\sigma,Q,S} \subset \mathbb{R}$ is the subset of real numbers that lies between the smallest and largest normal floating-point number:

$$\mathcal{N}_{\sigma,Q,S} := \{x : \min |F^{\mathrm{normal}}_{\sigma,Q,S}| \leq |x| \leq \max F^{\mathrm{normal}}_{\sigma,Q,S}\}$$

When σ, Q, S are implied by context we use the notation $\mathcal{N}$.

We can use machine epsilon to determine bounds on rounding:

Proposition 2 (round bound)**.** *If $x \in \mathcal{N}$ then*

$$\mathrm{fl}^{\mathrm{mode}}(x) = x(1+\delta^{\mathrm{mode}}_x)$$

where the relative error *is bounded by:*

$$|\delta^{\mathrm{nearest}}_x| \leq \frac{\epsilon_{\mathrm{m}}}{2}$$
$$|\delta^{\mathrm{up/down}}_x| < \epsilon_{\mathrm{m}}.$$

Proof

We will show this result for the nearest rounding mode. Note first that

$$\mathrm{fl}(-x) = -\mathrm{fl}(x)$$

and hence it suffices to prove the result for positive x. Write

$$x = 2^{q-\sigma}(1.b_1b_2\ldots b_S b_{S+1}\ldots)_2.$$

Define

$$x_- := \mathrm{fl}^{\mathrm{down}}(x) = 2^{q-\sigma}(1.b_1b_2\ldots b_S)_2$$
$$x_+ := \mathrm{fl}^{\mathrm{up}}(x) = x_- + 2^{q-\sigma-S}$$
$$x_{\mathrm{h}} := \frac{x_+ + x_-}{2} = x_- + 2^{q-\sigma-S-1} = 2^{q-\sigma}(1.b_1b_2\ldots b_S 1)_2$$

so that $x_- \leq x \leq x_+$. We consider two cases separately.

(**Round Down**) First consider the case where x is such that we round down: $\mathrm{fl}(x) = x_-$. Since $2^{q-\sigma} \leq x_- \leq x \leq x_\mathrm{h}$ we have

$$|\delta_x| = \frac{x - x_-}{x} \leq \frac{x_\mathrm{h} - x_-}{x_-} \leq \frac{2^{q-\sigma-S-1}}{2^{q-\sigma}} = 2^{-S-1} = \frac{\epsilon_\mathrm{m}}{2}.$$

(**Round Up**) If $\mathrm{fl}(x) = x_+$ then $2^{q-\sigma} \leq x_- < x_\mathrm{h} \leq x \leq x_+$ and hence

$$|\delta_x| = \frac{x_+ - x}{x} \leq \frac{x_+ - x_\mathrm{h}}{x_-} \leq \frac{2^{q-\sigma-S-1}}{2^{q-\sigma}} = 2^{-S-1} = \frac{\epsilon_\mathrm{m}}{2}.$$

■

This immediately implies relative error bounds on all IEEE arithmetic operations, e.g., if $x + y \in \mathcal{N}$ then we have

$$x \oplus y = (x + y)(1 + \delta_1)$$

where (assuming the default nearest rounding) $|\delta_1| \leq \frac{\epsilon_\mathrm{m}}{2}$.

II.2.2 Idealised floating point

With a complicated formula it is mathematically inelegant to work with normalised ranges: one cannot guarantee apriori that a computation always results in a normal float. Extending the bounds to subnormal numbers is tedious, rarely relevant, and beyond the scope of this module. Thus to avoid this issue we will work with an alternative mathematical model:

Definition 10 (idealised floating point)**.** An idealised mathematical model of floating point numbers for which the only subnormal number is zero can be defined as:

$$F_{\infty,S} := \{\pm 2^q \times (1.b_1 b_2 b_3 \dots b_S)_2 : q \in \mathbb{Z}\} \cup \{0\}$$

Note that $F^{\mathrm{normal}}_{\sigma,Q,S} \subset F_{\infty,S}$ for all $\sigma, Q \in \mathbb{N}$. The definition of rounding $\mathrm{fl}^{mode}_{\infty,S} : \mathbb{R} \to F_{\infty,S}$ naturally extend to $F_{\infty,S}$ and hence we can consider bounds for floating point operations such as $\oplus$, $\ominus$, etc. And in this model the round bound is valid for all real numbers (including $x = 0$).

Example 9 (bounding a simple computation)**.** We show how to bound the error in computing $(1.1 + 1.2) * 1.3 = 2.99$ and we may assume idealised floating-point arithmetic $F_{\infty,S}$. First note that `1.1` on a computer is in fact $\mathrm{fl}(1.1)$, and we will always assume nearest rounding unless otherwise stated. Thus this computation becomes

$$(\mathrm{fl}(1.1) \oplus \mathrm{fl}(1.2)) \otimes \mathrm{fl}(1.3)$$

We will show the *absolute error* is given by

$$(\mathrm{fl}(1.1) \oplus \mathrm{fl}(1.2)) \otimes \mathrm{fl}(1.3) = 2.99 + \delta$$

where $|\delta| \leq 23\epsilon_\mathrm{m}$. First we find

$$\begin{aligned} \mathrm{fl}(1.1) \oplus \mathrm{fl}(1.2) &= (1.1(1 + \delta_1) + 1.2(1 + \delta_2))(1 + \delta_3) \\ &= 2.3 + \underbrace{1.1\delta_1 + 1.2\delta_2 + 2.3\delta_3 + 1.1\delta_1\delta_3 + 1.2\delta_2\delta_3}_{\varepsilon_1}. \end{aligned}$$

While $\delta_1\delta_3$ and $\delta_2\delta_3$ are absolutely tiny in practice we will bound them rather naïvely by eg.

$$|\delta_1\delta_3| \leq \epsilon_{\mathrm{m}}^2/4 \leq \epsilon_{\mathrm{m}}/4.$$

Further we round up constants to integers in the bounds for simplicity (we won't be concerned here with deriving the sharpest error bounds). We thus have the bound

$$|\varepsilon_1| \leq (2+2+3+1+1)\frac{\epsilon_{\mathrm{m}}}{2} \leq 5\epsilon_{\mathrm{m}}.$$

Writing $\mathrm{fl}(1.3) = 1.3(1+\delta_4)$ and also incorporating an error from the rounding in $\otimes$ we arrive at

$$\begin{aligned}(\mathrm{fl}(1.1) \oplus \mathrm{fl}(1.2)) \otimes \mathrm{fl}(1.3) &= (2.3+\varepsilon_1)1.3(1+\delta_4)(1+\delta_5) \\ &= 2.99 + \underbrace{1.3(\varepsilon_1 + 2.3\delta_4 + 2.3\delta_5 + \varepsilon_1\delta_4 + \varepsilon_1\delta_5 + 2.3\delta_4\delta_5 + \varepsilon_1\delta_4\delta_5)}_{\delta}\end{aligned}$$

We use the bounds

$$\begin{aligned}|\varepsilon_1\delta_4|, |\varepsilon_1\delta_5| &\leq 5\epsilon_{\mathrm{m}}^2/2 \leq 5\epsilon_{\mathrm{m}}/2, \\ |\delta_4\delta_5| &\leq \epsilon_{\mathrm{m}}^2/4 \leq \epsilon_{\mathrm{m}}/4, \\ |\varepsilon_1\delta_4\delta_5| &\leq 5\epsilon_{\mathrm{m}}^3/4 \leq 5\epsilon_{\mathrm{m}}/4.\end{aligned}$$

Thus the *absolute error* is bounded (bounding 1.3 by 3/2) by

$$|\delta| \leq (3/2)(5+3/2+3/2+5/2+5/2+3/4+5/4)\epsilon_{\mathrm{m}} \leq 23\epsilon_{\mathrm{m}}.$$

II.2.3 Divided differences floating point error bound

We saw experimentally that divided differences resulted in a large error which was not consistent with the error bound derived assuming exact real arithmetic. Here we see how we can derive a bound incorporating the behaviour of floating point arithmetic, which reflects the large growth in error when h became small.

We assume that the function we are attempting to differentiate is computed using floating point arithmetic in a way that has a small absolute error.

Theorem 4 (divided difference error bound)**.** *Assume we are working in idealised floating-point arithmetic $F_{\infty,S}$. Let f be twice-differentiable in a neighbourhood of $x \in F_{\infty,S}$ and assume that*

$$f(x) = f^{\mathrm{FP}}(x) + \delta_x^f$$

where $f^{\mathrm{FP}} : F_{S,\infty} \to F_{S,\infty}$ has uniform absolute accuracy in that neighbourhood, that is:

$$|\delta_x^f| \leq c\epsilon_{\mathrm{m}}$$

for a fixed constant $c \geq 0$. The divided difference approximation partially implemented with floating point satisfies

$$\frac{f^{\mathrm{FP}}(x+h) \ominus f^{\mathrm{FP}}(x)}{h} = f'(x) + \delta_{x,h}^{\mathrm{FD}}$$

where

$$|\delta_{x,h}^{\mathrm{FD}}| \leq \frac{|f'(x)|}{2}\epsilon_{\mathrm{m}} + Mh + \frac{4c\epsilon_{\mathrm{m}}}{h}$$

for $M = \sup_{x \leq t \leq x+h} |f''(t)|$.

Proof

We have

$$(f^{\mathrm{FP}}(x+h) \ominus f^{\mathrm{FP}}(x))/h = \frac{f(x+h) - \delta^f_{x+h} - f(x) + \delta^f_x}{h}(1+\delta_1)$$
$$= \frac{f(x+h)-f(x)}{h}(1+\delta_1) + \frac{\delta^f_x - \delta^f_{x+h}}{h}(1+\delta_1)$$

where $|\delta_1| \leq \epsilon_{\mathrm{m}}/2$. Applying Taylor's theorem we get

$$(f^{\mathrm{FP}}(x+h) \ominus f^{\mathrm{FP}}(x))/h = f'(x) + \underbrace{f'(x)\delta_1 + \frac{f''(t)}{2}h(1+\delta_1) + \frac{\delta^f_x - \delta^f_{x+h}}{h}(1+\delta_1)}_{\delta^{\mathrm{FD}}_{x,h}}$$

The bound then follows, using the very pessimistic bound $|1+\delta_1| \leq 2$.

■

The previous theorem neglected some errors due to rounding, which was done for simplicity. This is justified under fairly general restrictions:

Corollary 2 (divided differences in practice)**.** *We have*

$$(f^{\mathrm{FP}}(x \oplus h) \ominus f^{\mathrm{FP}}(x)) \oslash h = \frac{f^{\mathrm{FP}}(x+h) \ominus f^{\mathrm{FP}}(x)}{h}$$

whenever $h = 2^{j-n}$ *for* $0 \leq n \leq S$ *and the last binary place of* $x \in F_{\infty,S}$ *is zero, that is* $x = \pm 2^j (1.b_1 \dots b_{S-1}0)_2$.

Proof

We first confirm $x \oplus h = x + h$. If $b_S = 0$ the worst possible case is that we increase the exponent by one as we are just adding 1 to one of the digits $b_1, \dots, b_S$. This would cause us to lose the last digit. But if that is zero no error is incurred when we round.

Now write $y := (f^{\mathrm{FP}}(x \oplus h) \ominus f^{\mathrm{FP}}(x)) = \pm 2^\nu (1.c_1 \dots c_S)_2 \in F_{\infty,S}$. We have

$$y/h = \pm 2^{\nu+n-j}(1.c_1 \dots c_S)_2 \in F_{\infty,S} \Rightarrow y/h = y \oslash h.$$

■

The three-terms of this bound tell us a story: the first term is a fixed (small) error, the second term tends to zero as $h \to 0$, while the last term grows like ϵ_{m}/h as $h \to 0$. Thus we observe convergence while the second term dominates, until the last term takes over. Of course, a bad upper bound is not the same as a proof that something grows, but it is a good indication of what happens *in general* and suffices to choose h so that these errors are balanced (and thus minimised). Since in general we do not have access to the constants c and M we employ the following heuristic to balance the two sources of errors:

Heuristic (divided difference with floating-point step) Choose h proportional to $\sqrt{\epsilon_{\mathrm{m}}}$ in divided differences so that Mh and $\frac{4c\epsilon_{\mathrm{m}}}{h}$ are (roughly) the same magnitude.

In the case of double precision $\sqrt{\epsilon_{\mathrm{m}}} \approx 1.5 \times 10^{-8}$, which is close to when the observed error begins to increase in the examples we saw before.

Remark While divided differences is of debatable utility for computing derivatives, it is extremely effective in building methods for solving differential equations, as we shall see

later. It is also very useful as a "sanity check" if one wants something to compare with other numerical methods for differentiation.

Remark It is also possible to deduce an error bound for the rectangular rule showing that the error caused by round-off is on the order of $n\epsilon_{\mathrm{m}}$, that is it does in fact grow but the error without round-off which was bounded by M/n will be substantially greater for all reasonable values of n.

II.2.4 Lab and problem sheet

In the lab we see how we can set the rounding mode of floating point calculations. This will set the ground-work for the next section where we implement interval arithmetic, which automatically computes rigorous error bounds. We also see that the `BigFloat` type allows for high-precision computations. In the problem sheet we bound the errors in some simple floating point expressions by-hand, and deduce an error bound for central differences capturing the impact of rounding. Finally, we see how addition and multiplication of many floating point numbers can also be bounded, which will lay the ground-work for understanding errors in linear algebra with floating point numbers.

II.3 Interval Arithmetic

We will now see how the details of floating point arithmetic give us a means of performing *computer-assisted proofs*, essentially turning the computer into a rigorous mathematician who can do millions (or even billions) of inequalities in seconds. To do this we will use the ability to set the rounding mode of floating point arithmetic to establish bounds. As an example we consider computing the digits of e with rigorous error bounds.

We first review set arithmetic. For sets $X, Y \subseteq \mathbb{R}$, the set arithmetic operations are defined as

$$\begin{aligned} X + Y &:= \{x + y : x \in X, y \in Y\}, \\ XY &:= \{xy : x \in X, y \in Y\}, \\ X/Y &:= \{x/y : x \in X, y \in Y\} \end{aligned}$$

We will use floating point arithmetic to construct approximate set operations $\oplus$, $\otimes$ so that

$$\begin{aligned} X + Y &\subseteq X \oplus Y, \\ XY &\subseteq X \otimes Y, \\ X/Y &\subseteq X \oslash Y \end{aligned}$$

thereby a complicated algorithm can be run on sets and the true result is guaranteed to be a subset of the output.

When our sets are intervals we can deduce simple formulæ for basic arithmetic operations. For simplicity we only consider the case where all values are positive, leaving the generalisation to the problem sheet.

Proposition 3 (interval bounds)**.** *For intervals $X = [a, b]$ and $Y = [c, d]$ satisfying $0 < a \leq b$*

and $0 < c \leq d$*, and* $n > 0$*, we have:*

$$\begin{aligned} X + Y &= [a + c, b + d] \\ X/n &= [a/n, b/n] \\ XY &= [ac, bd] \end{aligned}$$

Proof We first show $X + Y \subseteq [a + c, b + d]$. If $z \in X + Y$ then $z = x + y$ such that $a \leq x \leq b$ and $c \leq y \leq d$ and therefore $a + c \leq z \leq c + d$ and $z \in [a + c, b + d]$. Equality follows from convexity. First note that $a + c, b + d \in X + Y$. Any point $z \in [a + b, c + d]$ can be written as a convex combination of the two endpoints: there exists $0 \leq t \leq 1$ such that

$$z = (1 - t)(a + c) + t(b + d) = \underbrace{(1 - t)a + tb}_{x} + \underbrace{(1 - t)c + td}_{y}$$

Because intervals are convex we have $x \in X$ and $y \in Y$ and hence $z \in X + Y$.

The remaining two proofs are left for the problem sheet.

■

We want to implement floating point variants of these operations that are guaranteed to contain the true set arithmetic operations. We note that if we round the bottom of an interval down and the top of an interval up, then the actual interval is guaranteed to lie inside the resulting interval with rounded endpoints. We can implement this idea using rounded floating point arithmetic:

Definition 11 (floating point interval arithmetic)**.** For intervals $A = [a, b]$ and $B = [c, d]$ satisfying $0 < a \leq b$ and $0 < c \leq d$, and $n > 0$, define:

$$\begin{aligned} [a, b] \oplus [c, d] &:= [\mathrm{fl}^{\mathrm{down}}(a + c), \mathrm{fl}^{\mathrm{up}}(b + d)] \\ [a, b] \ominus [c, d] &:= [\mathrm{fl}^{\mathrm{down}}(a - d), \mathrm{fl}^{\mathrm{up}}(b - c)] \\ [a, b] \oslash n &:= [\mathrm{fl}^{\mathrm{down}}(a/n), \mathrm{fl}^{\mathrm{up}}(b/n)] \\ [a, b] \otimes [c, d] &:= [\mathrm{fl}^{\mathrm{down}}(ac), \mathrm{fl}^{\mathrm{up}}(bd)] \end{aligned}$$

We now explore this idea in pen-and-paper computations, in particular, to compute the exponential:

Example 10 (small sum)**.** consider evaluating the first few terms in the Taylor series of the exponential at $x = 1$ using interval arithmetic with half-precision F_{16} arithmetic. The first three terms are exact since all numbers involved are exactly floats, in particular if we evaluate $1 + x + x^2/2$ with $x = 1$ we get

$$1 + 1 + 1/2 \in 1 \oplus [1, 1] \oplus ([1, 1] \otimes [1, 1]) \oslash 2 = [5/2, 5/2]$$

Noting that

$$1/6 = (1/3)/2 = 2^{-3}(1.01010101\ldots)_2$$

we can extend the computation to another term:

$$\begin{aligned} 1 + 1 + 1/2 + 1/6 &\in [5/2, 5/2] \oplus ([1, 1] \oslash 6) \\ &= [2(1.01)_2, 2(1.01)_2] \oplus 2^{-3}[(1.0101010101)_2, (1.0101010110)_2] \\ &= [\mathrm{fl}^{\mathrm{down}}(2(1.0101010101\mathbf{0101})_2), \mathrm{fl}^{\mathrm{up}}(2(1.0101010101\mathbf{011})_2)] \\ &= [2(1.0101010101)_2, 2(1.0101010110)_2] \\ &= [2.666015625, 2.66796875] \end{aligned}$$

Example 11 (exponential with intervals)**.** Consider computing $\exp(x)$ for $0 \le x \le 1$ from the Taylor series approximation:

$$\exp(x) = \sum_{k=0}^{n} \frac{x^k}{k!} + \underbrace{\exp(t)\frac{x^{n+1}}{(n+1)!}}_{\delta_{x,n}}$$

where we can bound the error by (using the fact that $\mathrm{e} = 2.718\ldots \le 3$, an inequality whose proof we leave as an exercise)

$$|\delta_{x,n}| \le \frac{\exp(1)}{(n+1)!} \le \frac{3}{(n+1)!}.$$

Put another way: $\delta_{x,n} \in \left[-\frac{3}{(n+1)!}, \frac{3}{(n+1)!}\right]$. We can use this to adjust the bounds derived from interval arithmetic for the interval arithmetic expression:

$$\exp(X) \subseteq \left(\bigoplus_{k=0}^{n} X \oslash k \oslash k!\right) \oplus \left[\mathrm{fl}^{\mathrm{down}}\left(-\frac{3}{(n+1)!}\right), \mathrm{fl}^{\mathrm{up}}\left(\frac{3}{(n+1)!}\right)\right]$$

For example, with $n = 3$ we have $|\delta_{1,2}| \le 3/4! = 1/2^3$. Thus we can prove that:

$$\begin{aligned}\mathrm{e} &= 1 + 1 + 1/2 + 1/6 + \delta_x \in [2(1.0101010101)_2, 2(1.0101010110)_2] \oplus [-1/2^3, 1/2^3] \\ &= [2(1.0100010101)_2, 2(1.0110010110)_2] = [2.541015625, 2.79296875]\end{aligned}$$

II.3.1 Lab and Problem Sheet

In the lab we see how interval arithmetic with floating point numbers can be easily implemented by carefully setting the rounding mode. We also see how special functions like $\exp x$ can be implemented with rigorous bounds by combining computation with intervals with bounds on the Taylor series, turning the pen-and-paper example in these notes into an actual algorithm. As a fun example we compute $\exp 1 \equiv \mathrm{e}$ with rigorous bounds with as many as 1000 digits. This is a baby example of computer-assisted proofs, a concept that is increasingly important in pure mathematics and has been used for many important problems, including the proof of Kepler's conjecture, which was unsolved with non-computer-based techniques for 400 years.

In the problem sheet we complete the proofs of airthmetic with intervals and explore the rigorous computation of special functions like $\sin 1$ using interval arithmetic by-hand. This helps to build understanding on what the computer is doing in the labs.

Chapter III

Numerical Linear Algebra

Linear equations, especially ordinary and partial differential equations, are everywhere in applied mathematics, physics, and engineering. This is especially true in data science, eg., linear and polynomial regression for approximating data sets. Moreover, neural networks are built on top of linear algebra, with the basic layers being described in terms of matrix-vector products.

Numerical methods for linear equations invariably result in (finite-dimensional) linear systems that must be solved numerically on a computer: the dimensions of the problems are often in the 1000s, millions, or even billions. One would certainly not want to tackle that with Gaussian elimination by hand! In this chapter we discuss algorithms, and in particular matrix factorisations, that are computed using floating point operations. We also introduce some basic applications.

In particular we discuss:

1. III.1 Structured Matrices: we discuss special structured matrices such as triangular and tridiagonal.

2. III.2 LU and PLU Factorisations: we see that Gaussian elimination can be recast as computing a factorisation of a square matrix as a product of a lower and upper triangular matrix, potentially with a permutation matrix corresponding to the case where row pivoting is required.

3. III.3 Cholesky Factorisation: In the special case where the matrix is symmetric positive definite the LU factorisation has a special form. Hidden in this is an algorithm to prove positive definiteness.

4. III.4 Orthogonal Matrices: we discuss different types of orthogonal matrices, which will be used to simplify rectangular least squares problems.

5. III.5 QR Factorisation: we introduce an algorithm to compute a factorisation of a rectangular matrix as a product of an orthogonal and upper triangular matrix, thereby solving least squares problems.

Here we are constructing underlying computational tools that are important in applications, such as solving differential equations and data regression, which we discuss later.

III.1 Structured Matrices

We have seen how algebraic operations (`+`, `-`, `*`, `/`) are defined exactly in terms of rounding ($\oplus$, $\ominus$, $\otimes$, $\oslash$) for floating point numbers. Now we see how this allows us to do (approximate) linear algebra operations on matrices.

A matrix can be stored in different formats, in particular it is important for large scale simulations that we take advantage of *sparsity*: if we know a matrix has entries that are guaranteed to be zero we can implement faster algorithms. We shall see that this comes up naturally in numerical methods for solving differential equations.

In particular, we will discuss some basic types of structure in matrices:

1. *Dense*: This can be considered unstructured, where we need to store all entries in a vector or matrix. Matrix-vector multiplication reduces directly to standard algebraic operations. Solving linear systems with dense matrices will be discussed later.
2. *Triangular*: If a matrix is upper or lower triangular, multiplication requires roughly half the number of operations. Crucially, we can apply the inverse of a triangular matrix using forward- or back-substitution.
3. *Banded*: If a matrix is zero apart from entries a fixed distance from the diagonal it is called banded and matrix-vector multiplication has a lower *complexity*: the number of operations scales linearly with the dimension (instead of quadratically). We discuss three cases: diagonal, tridiagonal and bidiagonal matrices.

Remark For those who took the first half of the module, there was an important emphasis on working with *linear operators* rather than *matrices*. That is, there was an emphasis on basis-independent mathematical techniques, which is critical for extension of results to infinite-dimensional spaces (which might not have a complete basis). However, in terms of practical computation we need to work with some representation of an operator and the most natural is a matrix. And indeed we will see in the next chapter how infinite-dimensional differential equations can be solved by reduction to finite-dimensional matrices. (Restricting attention to matrices is also important as some of the students have not taken the first half of the module.)

III.1.1 Dense matrices

A basic operation is matrix-vector multiplication. For a field $\mathbb{F}$ (typically $\mathbb{R}$ or $\mathbb{C}$, or this can be relaxed to be a ring), consider a matrix and vector whose entries are in $\mathbb{F}$:

$$A = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{m1} & \cdots & a_{mn} \end{bmatrix} = \begin{bmatrix} \boldsymbol{a}_1 | \cdots | \boldsymbol{a}_n \end{bmatrix} \in \mathbb{F}^{m\times n}, \qquad \boldsymbol{x} = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix} \in \mathbb{F}^n.$$

where $\boldsymbol{a}_j = A\boldsymbol{e}_j \in \mathbb{F}^m$ are the columns of A. Recall the usual definition of matrix multiplication:

$$A\boldsymbol{x} := \begin{bmatrix} \sum_{j=1}^n a_{1j}x_j \\ \vdots \\ \sum_{j=1}^n a_{mj}x_j \end{bmatrix}.$$

When we are working with floating point numbers $A \in F^{m\times n}$ we obtain an approximation:

$$A\boldsymbol{x} \approx \begin{bmatrix} \bigoplus_{j=1}^n (a_{1j} \otimes x_j) \\ \vdots \\ \bigoplus_{j=1}^n (a_{mj} \otimes x_j) \end{bmatrix}.$$

This actually encodes an algorithm for computing the entries.

This algorithm uses $O(mn)$ floating point operations (see the appendix if you are unaware of Big-O notation, here our complexities are implicitly taken to be when m or n tends to ∞): each of the m entries consists of n multiplications and $n-1$ additions, hence we have a total of $2n-1 = O(n)$ operations per row for a total of $m(2n-1) = O(mn)$ operations. For a square matrix this is $O(n^2)$ operations which we call *quadratic complexity*. In the problem sheet we see how the floating point error can be bounded in terms of norms, thus reducing the problem to a purely mathematical concept.

Sometimes there are multiple ways of implementing numerical algorithms. We have an alternative formula where we multiply by columns:

$$A\boldsymbol{x} = x_1\boldsymbol{a}_1 + \cdots + x_n\boldsymbol{a}_n.$$

The floating point formula for this is exactly the same as the previous algorithm and the number of operations is the same. Just the order of operations has changed. Suprisingly, this latter version is significantly faster.

Remark Floating point operations are sometimes called FLOPs, which are a standard measurement of speed of CPUs. However, FLOP sometimes uses an alternative definitions that combines an addition and multiplication as a single FLOP. In the lab we give an example showing that counting the precise number of operations is somewhat of a fools errand: algorithms such as the two approaches for matrix multiplication with the exact same number of operations can have wildly different speeds. We will therefore only be concerned with *complexity*; the asymptotic growth (Big-O) of operations as $n \to \infty$, in which case the difference between FLOPs and operations is immaterial.

III.1.2 Triangular matrices

The simplest sparsity case is being triangular: where all entries above or below the diagonal are zero. We consider upper and lower triangular matrices:

$$U = \begin{bmatrix} u_{11} & \cdots & u_{1n} \\ & \ddots & \vdots \\ & & u_{nn} \end{bmatrix}, \qquad L = \begin{bmatrix} \ell_{11} & & \\ \vdots & \ddots & \\ \ell_{n1} & \cdots & \ell_{nn} \end{bmatrix}.$$

Matrix multiplication can be modified to take advantage of the zero pattern of the matrix. Eg., if $L \in \mathbb{F}^{n\times n}$ is lower triangular we have:

$$L\boldsymbol{x} = \begin{bmatrix} \ell_{1,1}x_1 \\ \sum_{j=1}^2 \ell_{2j}x_j \\ \vdots \\ \sum_{j=1}^n \ell_{nj}x_j \end{bmatrix}.$$

When implemented in floating point this uses roughly half the number of multiplications: $1 + 2 + \ldots + n = n(n+1)/2$ multiplications. (It is also about twice as fast in practice.) The complexity is still quadratic: $O(n^2)$ operations.

Triangularity allows us to also invert systems using forward- or back-substitution. In particular if $\boldsymbol{x}$ solves $L\boldsymbol{x} = \boldsymbol{b}$ then we have:

$$x_k = \frac{b_k - \sum_{j=1}^{k-1} \ell_{kj} x_j}{\ell_{kk}}$$

Thus we can compute $x_1, x_2, \ldots, x_n$ in sequence.

III.1.3 Banded matrices

A *banded matrix* is zero off a prescribed number of diagonals. We call the number of (potentially) non-zero diagonals the *bandwidths*:

Definition 12 (bandwidths)**.** A matrix A has *lower-bandwidth* l if $a_{kj} = 0$ for all $k - j > l$ and *upper-bandwidth* u if $a_{kj} = 0$ for all $j - k > u$. We say that it has *strictly lower-bandwidth* l if it has lower-bandwidth l and there exists a j such that $a_{j+l,j} \neq 0$. We say that it has *strictly upper-bandwidth* u if it has upper-bandwidth u and there exists a k such that $a_{k,k+u} \neq 0$.

A square banded matrix has the sparsity pattern:

$$A = \begin{bmatrix} a_{11} & \cdots & a_{1,u+1} & & & \\ \vdots & a_{22} & \ddots & a_{2,u+2} & & \\ a_{1+l,1} & \ddots & \ddots & \ddots & \ddots & \\ & a_{2+l,2} & \ddots & \ddots & \ddots & a_{n-u,n} \\ & & \ddots & \ddots & \ddots & \vdots \\ & & & a_{n,n-l} & \cdots & a_{nn} \end{bmatrix}$$

A banded matrix has better complexity for matrix multiplication and solving linear systems: we can multiply square banded matrices in linear complexity: $O(n)$ operations. We consider two cases in particular (in addition to diagonal): bidiagonal and tridiagonal.

Definition 13 (Bidiagonal)**.** If a square matrix has bandwidths $(l, u) = (1, 0)$ it is *lower-bidiagonal* and if it has bandwidths $(l, u) = (0, 1)$ it is *upper-bidiagonal*.

For example, if

$$L = \begin{bmatrix} \ell_{11} & & & \\ \ell_{21} & \ell_{22} & & \\ & \ddots & \ddots & \\ & & \ell_{n,n-1} & \ell_{nn} \end{bmatrix}$$

then lower-bidiagonal multiplication becomes

$$L\boldsymbol{x} = \begin{bmatrix} \ell_{1,1} x_1 \\ \ell_{21} x_1 + \ell_{22} x_2 \\ \vdots \\ \ell_{n,n-1} x_{n-1} + \ell_{nn} x_n \end{bmatrix}.$$

This requires $O(1)$ operations per row (at most 2 multiplications and 1 addition) and hence the total is only $O(n)$ operations. A bidiagonal matrix is always triangular and we can also invert in $O(n)$ operations: if $L\boldsymbol{x} = \boldsymbol{b}$ then $x_1 = b_1/\ell_{11}$ and for $k = 2, \dots, n$ we can compute

$$x_k = \frac{b_k - \ell_{k-1,k}x_{k-1}}{\ell_{kk}}.$$

Definition 14 (Tridiagonal)**.** If a square matrix has bandwidths $l = u = 1$ it is *tridiagonal*.

For example,

$$A = \begin{bmatrix} a_{11} & a_{12} & & & \\ a_{21} & a_{22} & a_{23} & & \\ & \ddots & \ddots & \ddots & \\ & & a_{n-1,n-2} & a_{n-1,n-1} & a_{n-1,n} \\ & & & a_{n,n-1} & a_{nn} \end{bmatrix}$$

is tridiagonal. Matrix multiplication is clearly $O(n)$ operations: each row has $O(1)$ non-zeros and there are n rows. But so is solving linear systems, which we shall see later.

III.1.4 Lab and Problem Sheet

In the lab we see how matrices and vectors can be constructed in Julia in multiple ways. We also see that there are different types to represent different structured matrices, including dense, diagonal, tridiagonal and bidiagonal, as well as a "lazy" transposes and range vectors (which can't be modified). We simple algorithms like computing matrix-vector multiplications are easily implemented, though there are some surprises: the order we access memory has a significant impact on the performance! Finally, we see how we can create our own types for representing structured matrices, in particular, we implement a type to represent an upper-tridiagonal matrix, including optimal complexity matrix-vector multiplication and linear solves.

The content of this section is largely explored in the lab. In the problem sheet, we look at understanding the effect of rounding error when using floating point arithmetic. This results in a very nice formula for the error of matrix-vector multiplication with floating point numbers in terms of a matrix norm. This is important as it allows us to understand the impact of floating point errors in terms of fundamental mathematical concepts (like norms).

Appendix A

Asymptotics and Computational Cost

We introduce Big-O, little-o and asymptotic notation and see how they can be used to describe computational cost.

A.1 Asymptotics as $n \to \infty$

Big-O, little-o, and "asymptotic to" are used to describe behaviour of functions at infinity.

Definition 15 (Big-O)**.**

$$f(n) = O(\phi(n)) \qquad (\text{as } n \to \infty)$$

means $\left|\frac{f(n)}{\phi(n)}\right|$ is bounded for sufficiently large n. That is, there exist constants C and N_0 such that, for all $n \geq N_0$, $|\frac{f(n)}{\phi(n)}| \leq C$.

Definition 16 (little-O)**.**

$$f(n) = o(\phi(n)) \qquad (\text{as } n \to \infty)$$

means $\lim_{n\to\infty} \frac{f(n)}{\phi(n)} = 0$.

Definition 17 (asymptotic to)**.**

$$f(n) \sim \phi(n) \qquad (\text{as } n \to \infty)$$

means $\lim_{n\to\infty} \frac{f(n)}{\phi(n)} = 1$.

Example 12 (asymptotics with n)**.** 1.

$$\frac{\cos n}{n^2 - 1} = O(n^{-2})$$

as

$$\left|\frac{\frac{\cos n}{n^2-1}}{n^{-2}}\right| \leq \left|\frac{n^2}{n^2-1}\right| \leq 2$$

for $n \geq N_0 = 2$.

2.
$$\log n = o(n)$$
as $\lim_{n\to\infty} \frac{\log n}{n} = 0$.

3.
$$n^2 + 1 \sim n^2$$
as $\frac{n^2+1}{n^2} \to 1$.

Note we sometimes write $f(O(\phi(n)))$ for a function of the form $f(g(n))$ such that $g(n) = O(\phi(n))$.

We have some simple algebraic rules:

Proposition 4 (Big-O rules)**.**
$$O(\phi(n))O(\psi(n)) = O(\phi(n)\psi(n)) \qquad (as\ n \to \infty)$$
$$O(\phi(n)) + O(\psi(n)) = O(|\phi(n)| + |\psi(n)|) \qquad (as\ n \to \infty).$$

Proof See any standard book on asymptotics, eg F.W.J. Olver, Asymptotics and Special Functions. ■

A.2 Asymptotics as $x \to x_0$

We also have Big-O, little-o and "asymptotic to" at a point:

Definition 18 (Big-O)**.**
$$f(x) = O(\phi(x)) \qquad (\text{as } x \to x_0)$$
means $|\frac{f(x)}{\phi(x)}|$ is bounded in a neighbourhood of x_0. That is, there exist constants C and r such that, for all $0 \le |x - x_0| \le r$, $|\frac{f(x)}{\phi(x)}| \le C$.

Definition 19 (little-O)**.**
$$f(x) = o(\phi(x)) \qquad (\text{as } x \to x_0)$$
means $\lim_{x\to x_0} \frac{f(x)}{\phi(x)} = 0$.

Definition 20 (asymptotic to)**.**
$$f(x) \sim \phi(x) \qquad (\text{as } x \to x_0)$$
means $\lim_{x\to x_0} \frac{f(x)}{\phi(x)} = 1$.

Example 13 (asymptotics with x)**.**
$$\exp x = 1 + x + O(x^2) \qquad \text{as } x \to 0$$
since $\exp x = 1 + x + \frac{\exp t}{2}x^2$ for some $t \in [0, x]$ and
$$\left|\frac{\frac{\exp t}{2}x^2}{x^2}\right| \le \frac{3}{2}$$
provided $x \le 1$.

A.3 Computational cost

We will use Big-O notation to describe the computational cost of algorithms. Consider the following simple sum

$$\sum_{k=1}^{n} x_k^2$$

which we might implement as:

```
function sumsq(x)
    n = length(x)
    ret = 0.0
    for k = 1:n
        ret = ret + x[k]^2
    end
    ret
end
```

```
sumsq (generic function with 1 method)
```

Each step of this algorithm consists of one memory look-up (`z = x[k]`), one multiplication (`w = z*z`) and one addition (`ret = ret + w`). We will ignore the memory look-up in the following discussion. The number of CPU operations per step is therefore 2 (the addition and multiplication). Thus the total number of CPU operations is $2n$. But the constant 2 here is misleading: we didn't count the memory look-up, thus it is more sensible to just talk about the asymptotic complexity, that is, the *computational cost* is $O(n)$.

Now consider a double sum like:

$$\sum_{k=1}^{n} \sum_{j=1}^{k} x_j^2$$

which we might implement as:

```
function sumsq2(x)
    n = length(x)
    ret = 0.0
    for k = 1:n
        for j = 1:k
            ret = ret + x[j]^2
        end
    end
    ret
end
```

```
sumsq2 (generic function with 1 method)
```

Now the inner loop is $O(1)$ operations (we don't try to count the precise number), which we do k times for $O(k)$ operations as $k \to \infty$. The outer loop therefore takes

$$\sum_{k=1}^{n} O(k) = O\left(\sum_{k=1}^{n} k\right) = O\left(\frac{n(n+1)}{2}\right) = O(n^2)$$

operations.

Appendix B

Integers

In this appendix we discuss the following:

1. Unsigned integers: how computers represent non-negative integers using only p-bits, via modular arithmetic.
2. Signed integers: how negative integers are handled using the Two's-complement format.

Mathematically, CPUs only act on p-bits at a time, with 2^p possible sequences. That is, essentially all functions f are either of the form $f : \mathbb{Z}_{2^p} \to \mathbb{Z}_{2^p}$ or $f : \mathbb{Z}_{2^p} \times \mathbb{Z}_{2^p} \to \mathbb{Z}_{2^p}$, where we use the following notation:

Definition 21 (finite integers)**.** Denote the set of the first m non-negative integers as $\mathbb{Z}_m := \{0, 1, \ldots, m-1\}$.

To translate between integers and bits we will need to write integers in binary format. That is, as sequence of `0`s and `1`s:

Example 14 (integers in binary)**.** A simple integer example is $5 = 2^2 + 2^0 = (101)_2$. On the other hand, we write $-5 = -(101)_2$. Another example is $258 = 2^8 + 2 = (100000010)_2$.

B.0.1 Unsigned Integers

Computers represent integers by a finite number of p-bits, with 2^p possible combinations of 0s and 1s. Denote these p-bits as $B_{p-1} \ldots B_1 B_0$ where $B_k \in \{0, 1\}$. For *unsigned integers* (non-negative integers) these bits dictate the first p binary digits: $(B_{p-1} \ldots B_1 B_0)_2$. Integers represented with p-bits on a computer are interpreted as representing elements of $\mathbb{Z}_{2^p}$ and integer arithmetic on a computer is equivalent to arithmetic modulo 2^p. We denote modular arithmetic with $m = 2^p$ as follows:

$$
\begin{aligned}
x \oplus_m y &:= (x + y) \pmod m \\
x \ominus_m y &:= (x - y) \pmod m \\
x \otimes_m y &:= (x * y) \pmod m
\end{aligned}
$$

When m is implied by context we just write $\oplus, \ominus, \otimes$. Note that the $(\text{mod } m)$ function simply drops all bits except for the first p-bits when writing a number in binary.

Example 15 (arithmetic with 8-bit unsigned integers)**.** If the result of an operation lies between 0 and $m = 2^8 = 256$ then airthmetic works exactly like standard integer arithmetic. For example,

$$17 \oplus_{256} 3 = 20 \pmod{256} = 20$$
$$17 \ominus_{256} 3 = 14 \pmod{256} = 14$$

Example 16 (overflow with 8-bit unsigned integers)**.** If we go beyond the range the result "wraps around". For example, with true integers we have

$$255 + 1 = (11111111)_2 + (00000001)_2 = (100000000)_2 = 256$$

However, the result is impossible to store in just 8-bits! So as mentioned instead it treats the integers as elements of $\mathbb{Z}_{256}$ by dropping any extra digits:

$$255 \oplus_{256} 1 = 255 + 1 \pmod{256} = (100000000)_2 \pmod{256} = 0.$$

On the other hand, if we go below 0 we wrap around from above:

$$3 \ominus_{256} 5 = -2 \pmod{256} = 254 = (11111110)_2$$

Example 17 (multiplication of 8-bit unsigned integers)**.** Multiplication works similarly: for example,

$$254 \otimes_{256} 2 = 254 * 2 \pmod{256} = (11111110)_2 * 2 \pmod{256} = (111111100)_2 \pmod{256} = 252.$$

Note that multiplication by 2 is the same as shifting the binary digits left by one, just as multiplication by 10 shifts base-10 digits left by 1.

B.0.2 Signed integer

Signed integers use the Two's complemement convention. The convention is if the first bit is 1 then the number is negative: in this case if the bits had represented the unsigned integer $2^p - y$ then the represent the signed integer $-y$. Thus for $p = 8$ we are interpreting 2^7 through $2^8 - 1$ as negative numbers. More precisely:

Definition 22 (signed integers)**.** Denote the finite signed integers as

$$\mathbb{Z}^{\mathrm{s}}_{2^p} := \{-2^{p-1}, \ldots, -1, 0, 1, \ldots, 2^{p-1} - 1\}.$$

Definition 23 (Shifted mod)**.** Define for $y = x \pmod{2^p}$

$$x \pmod[\mathrm{s}]{2^p} := \begin{cases} y & 0 \leq y \leq 2^{p-1} - 1 \\ y - 2^p & 2^{p-1} \leq y \leq 2^p - 1 \end{cases}$$

Note that if $R_p(x) = x \pmod[\mathrm{s}]{2^p}$ then it can be viewed as a map $R_p : \mathbb{Z} \to \mathbb{Z}^{\mathrm{s}}_{2^p}$ or a one-to-one map $R_p : \mathbb{Z}_{2^p} \to \mathbb{Z}^{\mathrm{s}}_{2^p}$ whose inverse is $R_p^{-1}(x) = x \pmod{2^p}$. It can also be viewed as the identity map on signed integers $R_p : \mathbb{Z}^{\mathrm{s}}_{2^p} \to \mathbb{Z}^{\mathrm{s}}_{2^p}$, that is, $R_p(x) = x$ if $x \in \mathbb{Z}^{\mathrm{s}}_{2^p}$.

Arithmetic works precisely the same for signed and unsigned integers up to the mapping R_p, e.g. we have for $m = 2^p$

$$x \oplus^{\mathrm{s}}_m y := (x + y) \pmod[\mathrm{s}]{m}$$
$$x \ominus^{\mathrm{s}}_m y := (x - y) \pmod[\mathrm{s}]{m}$$
$$x \otimes^{\mathrm{s}}_m y := (x * y) \pmod[\mathrm{s}]{m}$$

Example 18 (addition of 8-bit signed integers)**.** Consider `(-1) + 1` in 8-bit arithmetic:

$$-1 \oplus^{\mathrm{s}}_{256} 1 = -1 + 1 \ (\mathrm{mod}^{\mathrm{s}}\ 256) = 0$$

On the bit level this computation is exactly the same as unsigned integers. We represent the number -1 using the same bits as the unsigned integer $2^8 - 1 = 255$, that is using the bits `11111111` (i.e., we store it equivalently to $(11111111)_2 = 255$) and the number 1 is stored using the bits `00000001`. When we add this with true integer arithmetic we have

$$\begin{aligned}&(011111111)_2 \ +\\ &(000000001)_2 \ =\\ &(100000000)_2\end{aligned}$$

Modular arithmetic drops the leading 1 and we are left with all zeros.

Example 19 (signed overflow with 8-bit signed integers)**.** If we go above $2^{p-1}-1 = 2^7-1 = 127$ we have perhaps unexpected results:

$$127 \oplus^{\mathrm{s}}_{256} 1 = 128 \ (\mathrm{mod}^{\mathrm{s}}\ 256) = 128 - 256 = -128.$$

Again on the bit level this computation is exactly the same as unsigned integers. We represent the number 127 using the bits `01111111` and the number 1 is stored using the bits `00000001`. When we add this with true integer arithmetic we have

$$\begin{aligned}&(01111111)_2 \ +\\ &(00000001)_2 \ =\\ &(10000000)_2\end{aligned}$$

Because the first bit is `1` we interpret this as a negative number using the formula:

$$(10000000)_2 \ (\mathrm{mod}^{\mathrm{s}}\ 256) = 128(\mathrm{mod}^{\mathrm{s}}\ 256) = -128.$$

Example 20 (multiplication of 8-bit signed integers)**.** Consider computation of `(-2) * 2`:

$$(-2) \otimes^{\mathrm{s}}_{2^p} 2 = -4 \ (\mathrm{mod}^{\mathrm{s}}\ 2^p) = -4$$

On the bit level, the bits of -2 (which is one less than -1) are `11111110`. Multiplying by 2 is like multiplying by 10 in base-10, that is, we shift the bits. Hence in true arithmetic we have

$$\begin{aligned}&(011111110)_2 * 2 =\\ &(111111100)_2\end{aligned}$$

We drop the leading 1 due to modular arithmetic. We still have a leading 1 hence the number is viewed as negative. In particular we have

$$\begin{aligned}(111111100)_2 \ (\mathrm{mod}^{\mathrm{s}}\ 256) \ &= (11111100)_2 \ (\mathrm{mod}^{\mathrm{s}}\ 256) = 2^7 + 2^6 + 2^5 + 2^4 + 2^3 + 2^2 \ (\mathrm{mod}^{\mathrm{s}}\ 256)\\ &= 252 \ (\mathrm{mod}^{\mathrm{s}}\ 256) = -4.\end{aligned}$$

B.0.3 Hexadecimal format

In coding it is often convenient to use base-16 as it is a power of 2 but uses less characters than binary. The digits used are 0 through 9 followed by $a = 10$, $b = 11$, $c = 12$, $d = 13$, $e = 14$, and $f = 15$.

Example 21 (Hexadecimal number)**.** We can interpret a number in format as follows:

$$(a5f2)_{16} = a * 16^3 + 5 * 16^2 + f * 16 + 2 = 10 * 16^3 + 5 * 16^2 + 15 * 16 + 2 = 42,482$$

We will see in the labs that unsigned integers are displayed in base-16.

Appendix C

Permutation Matrices

Permutation matrices are matrices that represent the action of permuting the entries of a vector, that is, matrix representations of the symmetric group S_n, acting on $\mathbb{R}^n$. Recall every $\sigma \in S_n$ is a bijection between $\{1, 2, \ldots, n\}$ and itself. We can write a permutation σ in *Cauchy notation*:

$$\begin{pmatrix} 1 & 2 & 3 & \cdots & n \\ \sigma_1 & \sigma_2 & \sigma_3 & \cdots & \sigma_n \end{pmatrix}$$

where $\{\sigma_1, \ldots, \sigma_n\} = \{1, 2, \ldots, n\}$ (that is, each integer appears precisely once). We denote the *inverse permutation* by σ^{-1}, which can be constructed by swapping the rows of the Cauchy notation and reordering.

We can encode a permutation in vector $\sigma = [\sigma_1, \ldots, \sigma_n]$. This induces an action on a vector (using indexing notation)

$$\boldsymbol{v}[\sigma] = \begin{bmatrix} v_{\sigma_1} \\ \vdots \\ v_{\sigma_n} \end{bmatrix}$$

Example 22 (permutation of a vector)**.** Consider the permutation σ given by

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 \\ 1 & 4 & 2 & 5 & 3 \end{pmatrix}$$

We can apply it to a vector:

```
using LinearAlgebra
σ = [1, 4, 2, 5, 3]
v = [6, 7, 8, 9, 10]
v[σ] # we permutate entries of v

5-element Vector{Int64}:
  6
  9
  7
 10
  8
```

Its inverse permutation σ^{-1} has Cauchy notation coming from swapping the rows of the Cauchy notation of σ and sorting:

$$\begin{pmatrix} 1 & 4 & 2 & 5 & 3 \\ 1 & 2 & 3 & 4 & 5 \end{pmatrix} \to \begin{pmatrix} 1 & 2 & 4 & 3 & 5 \\ 1 & 3 & 2 & 5 & 4 \end{pmatrix}$$

Note that the operator

$$P_\sigma(\boldsymbol{v}) = \boldsymbol{v}[\sigma]$$

is linear in $\boldsymbol{v}$, therefore, we can identify it with a matrix whose action is:

$$P_\sigma \begin{bmatrix} v_1 \\ \vdots \\ v_n \end{bmatrix} = \begin{bmatrix} v_{\sigma_1} \\ \vdots \\ v_{\sigma_n} \end{bmatrix}.$$

The entries of this matrix are

$$P_\sigma[k,j] = \boldsymbol{e}_k^\top P_\sigma \boldsymbol{e}_j = \boldsymbol{e}_k^\top \boldsymbol{e}_{\sigma_j^{-1}} = \delta_{k,\sigma_j^{-1}} = \delta_{\sigma_k,j}$$

where $\delta_{k,j}$ is the *Kronecker delta*:

$$\delta_{k,j} := \begin{cases} 1 & k = j \\ 0 & \text{otherwise} \end{cases}.$$

This construction motivates the following definition:

Definition 24 (permutation matrix)**.** $P \in \mathbb{R}^{n\times n}$ is a permutation matrix if it is equal to the identity matrix with its rows permuted.

Proposition 5 (permutation matrix inverse)**.** *Let P_σ be a permutation matrix corresponding to the permutation σ. Then*

$$P_\sigma^\top = P_{\sigma^{-1}} = P_\sigma^{-1}$$

That is, P_σ is orthogonal*:*

$$P_\sigma^\top P_\sigma = P_\sigma P_\sigma^\top = I.$$

Proof

We prove orthogonality via:

$$\boldsymbol{e}_k^\top P_\sigma^\top P_\sigma \boldsymbol{e}_j = (P_\sigma \boldsymbol{e}_k)^\top P_\sigma \boldsymbol{e}_j = \boldsymbol{e}_{\sigma_k^{-1}}^\top \boldsymbol{e}_{\sigma_j^{-1}} = \delta_{k,j}$$

This shows $P_\sigma^\top P_\sigma = I$ and hence $P_\sigma^{-1} = P_\sigma^\top$.
